Bright and Dark Polar Deposits on Mercury: Evidence for Surface Volatiles

Measurements of surface reflectance of permanently shadowed areas near Mercury’s north pole reveal regions of anomalously dark and bright deposits at 1064-nanometer wavelength. These reflectance anomalies are concentrated on poleward-facing slopes and are spatially collocated with areas of high radar backscatter postulated to be the result of near-surface water ice. Correlation of observed reflectance with modeled temperatures indicates that the optically bright regions are consistent with surface water ice, whereas dark regions are consistent with a surface layer of complex organic material that likely overlies buried ice and provides thermal insulation. Impacts of comets or volatile-rich asteroids could have provided both dark and bright deposits.

Mercury’s near-zero obliquity and impact-roughened topography (1) prevent direct sunlight from reaching substantial portions of its polar regions. Lacking major convections or conductive sources of heat, the permanently shadowed, near-surface regolith experiences temperatures similar to those of the icy Galilean satellites (2). It has long been believed on theoretical grounds that such conditions are favorable to the accumulation of volatiles (3, 4). Even with Mercury’s close proximity to the Sun, extremes of daytime temperature are not expected to penetrate regolith to substantial depth, allowing near-surface water ice, if present, to remain stable against sublimation for billions of years (2). Such hypotheses were renewed when Earth-based radar observations of Mercury, at wavelengths from 3.6 to 70 cm (5–9), revealed regions of high backscatter and depolarization at both ends of the spectrum (2, 3). The neutron data, however, do not have the spatial resolution to distinguish regions of surface ice from the larger areas of shallowly buried ice. Furthermore, multielemental radar studies (10) suggest that polar deposits in the three largest north polar craters (Chesteron, Tolken, and Tryggvadottir (2)) that make a large contribution to the overall neutron signal are, on average, buried beneath a thin cover of dry soil or other comparatively ice-poor material.

Thus, the emplacement times implied by the neutron data represent an upper limit.

Acknowledgments: We thank the MESSENGER team for their contributions to the development and operation of the spacecraft, P. G. Lucey and two anonymous reviewers for comments that improved the manuscript, D. Delapp and D. Seagraves of Los Alamos National Laboratory for early help in the data reduction and calibration, respectively, and D. Hurley for discussions regarding surface modification models. This work was supported by the NASA Discovery Program, with funding for MESSENGER provided under contract NASS-97271 to the Johns Hopkins University Applied Physics Laboratory and NASW-00002 to the Carnegie Institution of Washington. Several authors are supported by NASA’s MESSENGER Participating Scientist Program. All original data reported in this paper are archived by the NASA Planetary Data System.

to 16 April 2012, densely sampling the north polar region in nadir mode northward to 83.5°N and sparsely in off-nadir mode at more northerly latitudes (Fig. 1A) (1). More than 4 million topographic and 2 million reflectance measurements were collected at latitudes greater than 65°N in the first year of mapping. Of 700 orbital profiles, 60 targeted latitudes higher than 84°N with off-nadir ranges, some yielding energy measurements and some not (fig. S1). Orbital geometry and power and thermal constraints precluded observations of many polar craters, and measurements of those that were accessible at oblique incidence returned noisier measurements than at nadir orientation.

A map of radar cross section in the north polar region at S-band (12.6-cm wavelength) (9) (Fig. 1B) shows many regions of high backscatter cross section; other such regions extend beyond the limits of the map to latitudes as low as 67°N. The polarization characteristics of these regions are suggestive of cold-trapped volatiles (5, 6, 18). These radar-bright (RB) features generally coincide with high-latitude, steep-walled craters of which the southern floors are permanently shadowed from direct sunlight because of Mercury’s near-zero obliquity. The largest RB features lie north of 85°N, whereas the 108-km-diameter Prokofiev crater [previously given the informal name “K” (18)] has a crescent-shaped RB region behind its steep (17° slope) north-facing wall, just south of 85°N (Fig. 1B). With a depth-to-diameter ratio of 0.025, typical for a complex crater of this size, only a portion of its floor can lie in permanent shadow, consistent with the shape of the RB region. An unnamed 1.5-km-deep, 18-km-diameter crater “Z” lies on the central floor of Prokofiev and is RB. The 62-km-diameter crater Kandinsky (formerly “J”) to the north has a nearly circular RB region (Fig. 1B). These and similar regions may now be subject to illumination models that use detailed polar topography (19).

A plot of the maximum illumination flux over 10 solar days is shown in Fig. 1C. We modeled the primary shadowing of the finite disk of the Sun with the orbital and rotational geometry of Mercury following an earlier methodology (20). Zero flux corresponds to areas of near-permanent shadow that receive only scattered light. Mercury’s orbital eccentricity and 3:2 spin-orbit resonance result in lower average solar flux near longitudes of 90° and 270°E. Shallow, degraded craters and craters lying near the 0° and 180°E longitudes of Mercury’s equatorial “hot poles” have higher average illumination. Except for relatively fresh craters on the northern smooth plains (1), there are few RB features along these azimuths south of 85°N.

The reflectance measurements binned at 1 km by 1 km resolution are shown in Fig. 1D. The log-normally distributed quantity $r_\text{s}$ has a mean of $0.17 \pm 0.05$ (SD), and 98% of returns have $r_\text{s} < 0.3$ (fig. S1). For comparison, the broadband geometric albedo of Mercury from space is 0.142 (21). About 7% of returns comprise a secondary “MLA-dark” (MD) mode distinguished by $r_\text{s} < 0.1$. This mode is seen in regions that are markedly darker than their surroundings. These regions coincide with areas where many received pulses do not trigger at the high threshold (fig. S2), although weak laser output, oblique incidence, steep terrain, and/or extreme range, as well as low reflectivity, can lead to poor signal recovery. The deficit of energy measurements in many MD regions indicates that the measured $r_\text{s}$ values are upper bounds for surface albedoes that are lower by factors of 2 to 3 than their surroundings.

Many of the MD regions are associated with polar craters containing RB material (Fig. 2). The larger MD regions generally enclose the RB features. MD returns lie mainly within regions of very low peak illumination, although not necessarily permanent shadow. The reflectance is low

![Fig. 1. Maps of topography, radar cross section, solar illumination, and reflectance in polar stereographic projection southward to 75°N. Kandinsky and Prokofiev craters are outlined in three of the four panels. (A) Topography (color scale in km) and shaded relief; the datum is a sphere of radius 2440 km. (B) Earth-based radar image (9) displayed as a dimensionless radar cross section per unit area. (C) Maximum incident solar flux over a 10-year period as a percentage of the solar constant at 1 astronomical unit (AU) from an illumination model. The red box outlines the region shown in Fig. 2. (D) The 1064-nm bidirectional reflectance from MLA low- and high-threshold measurements in near-nadir directions, median-averaged in 1 km—by—1 km bins. At latitudes poleward of 84°N, MLA obtained only a limited number of off-nadir profiles, and the projected reflectance data in this region are interpolated by a nearest-neighbor weighted average only within 2 km of data whose incidence angles were less than 10°.

over the southern floors and the northward-facing walls of virtually all craters at latitudes between 75° and 84°N. Darkening also occurs on some poleward-facing exterior rim slopes of craters in the otherwise smooth plains within the 320-km-diameter Goethe basin. Such darkening extends into regions that are partially illuminated.

The asymmetric distribution of MD regions with respect to terrain slope direction does not simply result from observing geometry, surface roughness, or the magnitude of the surface slope. The pulses returning from the MD portions are not noticeably wider or narrower than those from the illuminated portions, nor do equator-facing portions of the floor show lower reflectance. If surface slope or roughness were causing reduced energy return, the darker regions would have a circular outline. The correspondence of dark material with pole-facing slopes and the lack of such darkening in most craters southward of 70°N appears to rule out instrumental effects or observational geometry as a cause of the surficial darkening.

To assess the relations between MLA-dark features, RB deposits, and illumination, we examined (22) 175 regions of low illumination identified as lying within craters varying in size from ~7 to 108 km in diameter (23) and from 65°N poleward (Table 1). All craters with RB deposits and sufficient MLA sampling show at least some MD features in their poleward-facing portions. Of 128 RB craters with RB deposits, 96 contain collocated MD portions, whereas there are 28 additional craters with MD material that lack a corresponding RB signature. Two such craters (b5 and f5) (Fig. 2 and fig. S3) are relatively pristine (>1 km deep), so their interiors may not be visible to Earth-based radar. Twelve such craters are <14 km in diameter. Those craters with MD material that lack a RB signature and are 14 km or larger in diameter are at latitudes south of 80°N. As with the RB regions, MLA-dark deposits are more prevalent near 90° and 270°E, longitudes that receive less average illumination as a result of Mercury’s spin-orbit resonance and eccentric orbit, and in fresh craters on the smooth plains. At latitudes north of 75°N, 15 similar shadowed regions (putatively small craters) with neither a RB signature nor MD material are located mainly on an elevated area surrounding Purcell crater between longitudes 170° and 230°E. Radar coverage may be partial.

**Fig. 2.** Regional view of the area outlined in Fig. 1, in polar stereographic projection. Red circles show the outlines of six craters. (A) Maximum incident solar flux, as a percentage of the solar constant at 1 AU. (B) Radar cross-section per unit area. The projected radar map (9) has been shifted by 4 km to account for differences in projection and to achieve optimal registration with the MLA-based maps. Regions of interest (22) are labeled. (C) MLA reflectance (colored dots).

**Fig. 3.** (A) MLA reflectance measurements (colored dots) of the north polar region from longitude 0° to 90°E and latitude 82.5° to 90°N. Background is a mosaic of MDIS (34) frames at different illumination geometries and has a nonlinear contrast stretch for visibility. Three profiles through Prokofiev (b-b′, c-c′, and d-d′) were acquired at near-nadir orientation. Profiles through Kandinsky were acquired at ~30° off-nadir orientation. (B to D) Profiles of height (black lines) and reflectance (red dots) through Prokofiev acquired on 22 through 24 March 2012 starting at 0308 UTC on each day, at a 5° to 7° nadir angle. Vertical exaggeration is 10:1. The profiles are centered at longitude 60°E and traverse the poleward-facing wall of Prokofiev crater in an approximate west-to-east direction. The blue lines show the modeled extent of low average solar flux (<50 W m⁻² or <0.04 of terrestrial).
ly obscured by rough terrain in this sector, but the lack of RB features more likely has a thermal origin at these “hot pole” longitudes in locations where partial illumination might preclude stability of near-surface water ice (fig. S4).

Although the MLA-dark regions are more abundant and extensive than RB regions, there are at least nine areas within the largest RB regions at very high latitudes in which the MLA reflectances are optically bright. The nine craters hosting RB material, at latitudes between 82.5° and 88.5°N, have portions with \( r_s > 0.3 \) as well as areas that are anomalously dark or that return no reflectance measurements. The two most prominent such craters are north of 84.9°N latitude.

Craters Kindinsky and Prokofiev, for which high radar cross sections suggest thick, near-surface ice deposits (18), are shown in Fig. 3. Their regions of permanent shadow (Fig. 1C) have many reflectance values in excess of 0.3 (pink or white symbols), especially along the southern portion of Prokofiev. Three profiles crossing the RB region are plotted along track in Fig. 3, B to D. Profile 3B grazed the uppermost kilometer of the crater wall and recorded no high-threshold detections in regions of shadow. Profile 3C passed 2 km into the interior along the north-facing wall and shows many strongly reflective returns (red symbols) up to the edges of the crater, where such returns dropped out for several seconds. Profile 3D reached portions of the crater floor that are in permanent shadow and recorded variable reflectance. These profiles are the only ones to date obtained over the shadowed interior of Prokofiev at the relatively small incidence angles (6° to 7°) for which reflectance measurements are most reliable. Two profiles nearest to crater Z (Fig. 3A) also include returns with \( r_s > 0.3 \), as do several traversing crater Kindinsky to the north, but the measurements are noisier owing to incidence angles greater than 25°.

The observations of 1064-nm reflectance from laser altimetry thus fall into three categories: Most are typical of Mercury reflectivity as a whole; a subset is much darker; and a smaller subset is substantially brighter. The association of MD regions with RB regions in near-permanent shadow suggests that a thin, radar-transparent layer of optically dark material overlies and surrounds the postulated polar ice deposits. If water ice were present in the ground as a matrix between mineral grains, it could lower the reflectance relative to dry ground but would sublimate rapidly and lose optical contrast if exposed to high temperatures. The presence of MD regions in many smaller craters without RB deposits, areas where scattered light raises average temperatures (2, 24), indicates the presence of volatiles that are both darker than water ice and stable to higher temperatures.

The identification of optically bright regions associated with large RB features at the highest (>84.9°N) latitudes is consistent with the hypothesis that water ice is exposed at the surface in areas where surface temperatures are never sufficiently high for substantial loss by sublimation. The surface measurements are averages over footprints that are dozens of meters in extent and could represent a thin or unevenly distributed layer of optically bright material that has not been covered by dust or regolith. However, to the extent that MLA-bright and RB characteristics are sampling the same material, the associated deposits must have a thickness of at least several meters. The reflectance measurements presented here strongly suggest that one of the largest and deepest regions of permanent shadow in crater Prokofiev is a host for water ice deposits exposed at the surface.

The existence of these dark and bright surfaces and their association with topography indicates that their formation processes operated during geologically recent times and may be active on Mercury today. The rates of darkening and brightening must be higher than those for processes that act to homogenize surface reflectance, such as impact gardening. Vertical mixing by impact gardening dominant at the meter scale, we would expect that the polar deposits would have reflectance values (and radar backscatter characteristics) more similar to those of surrounding terrain.

Detailed thermal models (25) suggest that surface temperatures in the majority of the high-latitude craters with RB deposits that MLA has observed to date are too warm to support persistent water ice at the surface, but the temperatures in their shadowed areas are compatible with the presence of surficial dark organic material. Modeled subsurface temperatures in these dark regions are permissive of stable water ice beneath a ~10-cm-thick layer of thermally insulating material. In contrast, thermal modeling of the bright areas is supportive of surface water ice. This interpretation of the surface reflectance at 1064 nm is consistent with the radar results as well as with neutron spectroscopic measurements of Mercury’s polar regions (26). The bright and dark areas can be ascribed collectively to the deposition of water and organic volatiles derived from the impacts of comets or volatile-rich asteroids on Mercury’s surface and migrated to polar cold traps via thermally stimulated random walk (27–29).

References and Notes
9. The MLA is a time-of-flight laser range finder that uses direct detection and pulse-edge timing to determine precisely the range from the MESSENGER spacecraft to Mercury’s surface. MLA’s laser transmitter emits 6-ns-long pulses at an 8-Hz rate with 20 mJ of energy at a wavelength of 1064 nm. Return echoes are collected by an array of four refractive telescopes and are detected with a single silicon avalanche photodiode detector. The timing of laser pulses is measured with a set of time-to-digital converters linked to a crystal oscillator for which the frequency is monitored from Earth.
Thermal Stability of Volatiles in the North Polar Region of Mercury

Thermal models for the north polar region of Mercury, calculated from topographic measurements made by the MESSENGER spacecraft, show that the spatial distribution of regions of high radar backscatter is well matched by the predicted distribution of thermally stable water ice. MESSENGER measurements of near-infrared surface reflectance indicate bright surfaces in the coldest areas where water ice is predicted to be stable at the surface, and dark surfaces within and surrounding warmer areas where water ice is predicted to be stable only in the near subsurface. We propose that the dark surface layer is a sublimation lag deposit that may be rich in impact-derived organic material.

Earth-based radar observations have yielded maps of anomalously bright, depolarizing features on Mercury that appear to be localized in permanently shadowed regions near the planet’s poles (1, 2). Observations of similar radar signatures over a range of radar wavelengths imply that the radar-bright features correspond to deposits that are highly transparent at radar wavelengths and extend to depths of several meters below the surface (3). Cold-trapped water ice has been proposed as the most likely material to be responsible for these features (2, 4, 5), but other volatile species that are abundant on Mercury, such as sulfur, have also been suggested (6).

Measurements of surface reflectance at a wavelength of 1064 nm, made with the Mercury Laser Altimeter (MLA) onboard the MESSENGER spacecraft, show that the spatial distribution of regions of high radar backscatter is well matched by the predicted distribution of thermally stable water ice. Wet Mercury

Radar observations of Mercury's poles in the 1990s revealed regions of high backscatter that were interpreted as indicative of thick deposits of water ice; however, other explanations have also been proposed (see the Perspective by Lucey). MESSENGER neutron data reported by Lawrence et al. (p. 292, published online 29 November) in conjunction with thermal modeling by Paige et al. (p. 300, published online 29 November) now confirm that the primary component of radar-reflective material at Mercury's north pole is water ice. Neumann et al. (p. 296, published online 29 November) analyzed surface reflectance measurements from the Mercury Laser Altimeter onboard MESSENGER and found that while some areas of high radar backscatter coincide with optically bright regions, consistent with water ice exposed at the surface, some radar-reflective areas correlate with optically dark regions, indicative of organic sublimation lag deposits overlying the ice. Dark areas that fall outside regions of high radio backscatter suggest that water ice was once more widespread.
